## Abstract

Experimental investigation of floating structures represents the most direct way for achieving their dynamic identification and it is particularly valuable for relatively new concepts, such as floating supports for offshore wind turbines, in order to fully understand their dynamic behaviour. Traditional experimental campaigns on floating structures are carried out at small scale, in indoor laboratories, equipped with wave and wind generation facilities. This article presents the results of a 1:30 open-sea experimental activity on a scale model of the OC3-Hywind spar, in parked rotor conditions, carried out at the Natural Ocean Engineering Laboratory (NOEL) of Reggio Calabria (Italy). The aim of the experiment is two-fold. Firstly, it aims to assess the feasibility of low-cost, intermediate-scale, open-sea activities on offshore structures, which are proposed to substitute or complement the traditional indoor activities in ocean basins. Secondly, it provides useful experimental data on damping properties of spar support structures for offshore wind turbines, with respect to heave, roll and pitch degrees of freedom. It has been proven that the proposed approach may overcome some limitations of traditional small-scale activities, namely high costs and small scale, and allows to enhance the fidelity of the experimental data currently available in literature for spar floating supports for offshore wind turbines.

## Keywords

3. Floating wind turbines
4. Physical model
5. Heave damping
6. Roll damping

## Introduction

Nowadays, floating structures are used by several industries, including oil & gas, renewables (wind, wave, tidal), ports, and others, while the development and spread of many further concepts is envisaged to take place in a near future [1]. In the case of offshore wind industry, several advantages in moving offshore wind energy production towards deep waters can be exploited, including the availability of larger areas, stronger and steadier winds, and the reduction of visual and acoustic impact. However, the development of such concepts requires a significant amount of research in multiple areas of knowledge, including the

development of reliable dynamic models, able to represent the coupled behaviour of the floating wind turbines [2-3]. While such models are usually implemented by means of numerical codes [4-5], experimental activities play a crucial role for their validation, as well as for the system identification.

The experimental activities on floating offshore wind turbines may be classified in two groups, namely small-scale and large-scale ones. Traditional small-scale activities (1:50-1:100) are carried out in controlled environment such as wave tanks and ocean basins, where the desired wind-wave conditions can be reproduced, to measure the dynamic response of the structure and to calibrate opportunely the numerical codes [6-8]. Although the controlled environment allows to achieve very precise and reliable results, these activities have some relevant disadvantages, namely high rental fees of the basins, limited duration of the experiments, and limitations in representing all the relevant physical phenomena at scale level, which may alter significantly the dynamic behaviour of the model with respect to the full-scale structure. On the opposite side, large-scale activities (1:1-1:10) are carried out in open-sea and allow to represent all the relevant features of the offshore wind turbines, including turbine-support interaction, mooring system and grid connection, in relevant operational conditions [9-11]. Clearly, such projects are very expensive and usually represent pilot activities, which are carried out by big companies and/or public bodies for demonstration and commercial purposes, and whose results are rarely publicly available.

## 1.1 Literature review

Up to now, several small-scale and large-scale experimental activities have been conducted on spar support structures for offshore wind turbines, aimed to prove the feasibility of the concept and validate the corresponding numerical models. A full-scale prototype of a 2.3 MW spar floating offshore wind turbine was installed in 2009 by Statoil [12], off the coast of Norway, on a water depth of about 200 m. The project, called "Hywind Demo", has proved the technical feasibility of the spar configuration for floating offshore wind turbines, but neither the detailed design characteristics of the offshore wind turbine, nor the recorded field data are publicly available. In 2006, a 1:47 scale model of a 5-MW spar floating wind turbine was tested by Nielsen et al. [13] at the Ocean Basin Laboratory of Marintek, in Trondheim (Norway). The model was tested in irregular waves and turbulent wind speed and various control strategies were adopted. The experimental data showed relatively good agreement with the numerical results obtained in SIMO/RIFLEX, however some information were not released, concerning the detailed characteristics of the model. In 2010, the Offshore Code Comparison (OC3) project [4] was established to verify the accuracy and correctness of the most commonly used numerical codes for coupled analysis of offshore wind turbines. Within this project, the OC3-Hywind spar buoy [14] was defined as the reference spar concept designed to support the NREL-5MW reference offshore wind turbine [15]. Since then, this concept has been widely used for experimental studies on offshore wind turbines, since Statoil's Hywind characteristics are not released for public use. In 2011, a 1:128 scale model of the OC3-Hywind platform was tested by Shin [16] at the Ocean Engineering Wave Tank of the University of Ulsan (South Korea). The experiment was conducted under various environmental conditions, including regular waves, associated to constant wind speed and rotating rotor, and irregular waves, associated to fixed rotor. Response Amplitude Operators (RAOs) and significant motions were obtained and compared to numerical predictions obtained using FAST and MOSES codes. In 2010, the Japanese Ministry of Environment started a national demonstration project which led to the installation of a 1:2.35 (2012) and a 1:1 (2013) grid-connected 100 kW and 2 MW spar wind turbines off Goto Islands (Japan), preceded by the testing of a 1:100 scale model, in the offshore structure basin of National Maritime Research Institute (NMRI) in Tokyo (Japan), and of a 1:10 model at sea [9-10,17]. The small-scale test was aimed to study the dynamic behaviour of the model, particularly concerning the effects of blade-pitch control, under regular and irregular waves and constant wind speed. The 1:10 model was

83 aimed to further assess the safety and the performances of the chosen concept. Limited information are  
84 available concerning the 1:1 test activity, while experimental data collected in 2012 during a severe  
85 typhoon were compared to numerical predictions in FAST by Utsunomiya et al. [18], revealing quite good  
86 agreement. In 2012, a 1:50 scale-model of a spar floating wind turbine was tested within a project  
87 conducted by the University of Maine [19-20], aimed to compare it with a semi-submersible and a Tension-  
88 Leg Platform model. The three models were tested at Maritime Research Institute Netherlands (MARIN) in  
89 Wageningen (Netherlands) under various wind-wave conditions, including dynamic wind and bi-directional  
90 sea states. Full system identification was achieved, including estimation of the damping ratios and the  
91 RAOs. In 2013, a 1:100 scale model of a stepped-spar was tested by Sethumaran and Venugopal [21] at the  
92 curved wave tank of the University of Edinburgh (Scotland, UK). Only hydrodynamic behaviour of the model  
93 was investigated through regular and irregular wave tests and the experimental results in the frequency  
94 (RAOs) and time domain were compared to numerical predictions obtained using Orcaflex code. Also,  
95 different mooring systems were tested and their performances were compared. In 2016, a 1:50 scale model  
96 of OC3-Hywind spar was tested at MARIN by Duan et al. [22], who obtained response spectra for various  
97 load combinations and provided a deeper insight on the coupled dynamics of spar floating wind turbines.  
98 All these activities provided useful experimental results on the spar dynamic behaviour, but suffered from  
99 the above-mentioned limitations, in particular concerning the relatively high costs associated to basin  
100 rental, the restrictions in experimental duration and the insurgence of scale effects.

## 101 1.2 Aim

102 The purpose of this paper is to present the results of a 1:30 scale experimental activity on a spar floating  
103 support for offshore wind turbines, carried out near shore at the Natural Ocean Engineering Laboratory  
104 (NOEL) of Reggio Calabria (Italy). The support model tested is inspired to OC3-Hywind and has been  
105 represented in parked rotor conditions. The experimental activities carried out during this campaign were  
106 aimed at addressing and solving some of the problems inherent to the traditional experimental activities in  
107 ocean basins (some initial results were published in references [23-24]).

108 In recognition of the fact that the well-known identification techniques adopted in indoor laboratories must  
109 be modified to work in a non-controlled marine environment, this paper offers a broad-wide overview  
110 about the requirements, test methodologies, instrumentations and identification methods necessary for  
111 operating dynamic identification of offshore floating structures' intermediate-scale models in open-sea  
112 conditions. Then, the results obtained from the free decay tests and the irregular wave tests performed on  
113 the 1:30 spar structure are presented in terms of RAOs, damping coefficients and significant motions in  
114 heave, roll and pitch, in order to calibrate a numerical model of the structure implemented through the  
115 software Ansys AQWA [25-26]. These experimental data represent valuable and original information on the  
116 hydrodynamic behaviour of the OC3-Hywind platform, since the scale factor chosen for the model is  
117 sufficiently high to minimize the scale effects in the representation of wave forces. Finally, the feasibility of  
118 the new approach proposed is discussed and its main advantages and limitations are outlined.

119

## 120 Experimental set-up

### 121 2.1 Suitable test site characteristics

122 The choice of the test site is a crucial step for the arrangement of intermediate-scale, open-sea,  
123 experimental activities, since local wind-wave conditions must fulfil some restrictive requirements. First of  
124 all, the local waves at the test site must be representative of the full-scale conditions, according to Froude  
125 scaling laws. As observed by Boccotti [27], such a condition can be obtained if the wave spectrum of the

126 model waves is a scale model of the design spectrum at all the water depths. Such a requirement is  
127 particularly important when dealing with deep-drafted structures, such as spar buoys, and is challenging to  
128 achieve in open sea, since smaller sea states are usually made up of wind-generated waves superimposed  
129 by swells, which have a higher impact on the water particle kinematics at deeper levels and alter  
130 significantly the similitude with respect to full-scale wind-generated design sea states. On the other hand, it  
131 is known that, while small wind-generated sea states are essential for modelling the dynamic response in  
132 Froude scale, confused and mixed sea-states play a crucial role for the realization of this kind of  
133 experimental activities. Indeed, although they do not represent in scale any realistic condition, they allow  
134 to investigate the response of the model structure over a larger frequency range, possibly close to its  
135 natural frequencies, so that estimation of RAOs and damping coefficients can be achieved. Finally, the test  
136 site should present other characteristics, favourable for field experiment activities [27].

137 The test site chosen for the present study is the Natural Ocean Engineering Laboratory (NOEL), located in  
138 the sea front of Reggio Calabria (Italy), on the eastern coast of Messina's Strait (LAT 38°06.538'N; LONG  
139 15°38.478'E) (Fig.1). The site is particularly favourable for the selected case study, since it presents small  
140 wind-generated sea states with significant wave heights  $H_s$  between 0.20 m and 0.40 m, peak periods  $T_p$   
141 between 1.8 s and 2.6 s and JONSWAP-like spectra, which occur regularly, as well as the required variety of  
142 wave loading condition for model identification over a relatively large frequency range. The realization of  
143 these sea states is due to the unique environmental and geographical characteristics of the area, i.e. the  
144 local NNW wind, blowing from Sicily with a high stability, the orientation of the coast from SW to NE,  
145 sheltering the swells coming from South and the relatively small fetch, which is about  $10^4$  m. Finally, the  
146 tide amplitude is within 0.1 m: such a small value is of crucial importance for experimental testing of  
147 offshore structures, since larger variations of the water depth may affect significantly the operation of the  
148 mooring system. A detailed description of the test site metocean conditions is available in ref. [27-29]

149

## 151 2.2 Importance of scale effects for spar structures

152 The Froude scaling laws, in terms of the variables of interest for the scale models of floating wind turbines,  
153 are reported in Table 1.

154

155 Table 1 – Froude scaling laws for physical models of offshore wind turbines

Parameter	Scale factor	Units
Length	$\lambda_L$	m
Angle	$\lambda_\theta = 1$	rad
Time	$\lambda_T = \lambda_L^{0.5}$	s
Velocity	$\lambda_v = \lambda_L^{0.5}$	m s <sup>-1</sup>
Angular velocity	$\lambda_\omega = \lambda_L^{-0.5}$	rad s <sup>-1</sup>
Acceleration	$\lambda_a = 1$	m s <sup>-2</sup>
Density	$\lambda_\rho = 1$	kg m <sup>-3</sup>
Mass	$\lambda_m = \lambda_L^3$	kg
Mass moment of inertia	$\lambda_I = \lambda_L^5$	kg m <sup>2</sup>
Force	$\lambda_F = \lambda_L^3$	N
Power	$\lambda_P = \lambda_L^{3.5}$	W
Keulegan-Carpenter number	$\lambda_K = 1$	-
Reynolds number	$\lambda_R = \lambda_L^{1.5}$	-

156 In Table 1, Keulegan-Carpenter number  $K_C$  and Reynolds number  $R_e$  are defined as functions of the  
 157 maximum wave velocity  $v_{max}$ , a characteristic wave period  $T$ , which is usually identified as the peak period  
 158 of the sea state, a characteristic length of the structure  $D$ , which is usually identified as its diameter, and  
 159 the water kinematic viscosity  $\nu$ :

160 
$$K_C = \frac{v_{max} T}{D} \quad (1)$$

161 
$$R_e = \frac{v_{max} D}{\nu} \quad (2)$$

162 As Froude scale inevitably alters Reynolds number  $R_e$ , several challenges arise in the scale representation of  
 163 the wind turbine and support hull. Since in this work only the parked rotor conditions will be investigated, a  
 164 detailed treatment of the scaling procedures regarding the wind turbine will not be further discussed, see  
 165 for example [30-32]. Regarding the hull, wave-structure interaction depends on the relative size of the  
 166 structure with respect to the wavelength. Morison's equation [33] can be adopted when the spar radius  $R$  is  
 167 smaller than  $0.10L$ , being  $L$  a characteristic wave length, representative of the sea state [34]. According to  
 168 Jonkman, [14], such a condition is fulfilled for all the most relevant operational and ultimate conditions of  
 169 the OC3-Hywind spar buoy, hence the unit wave force vector on the hull may be expressed as the following  
 170 function of the vertical distance  $z$  from still water level:

171 
$$\begin{aligned} \mathbf{f}(z, t) = & (1 + C_a) \rho \pi R^2(z) \mathbf{a}(z, t) - C_a \rho \pi R^2(z) \ddot{\mathbf{u}}(z, t) + \\ & + C_d \rho R(z) |\mathbf{v}(z, t) - \dot{\mathbf{u}}(z, t)| [\mathbf{v}(z, t) - \dot{\mathbf{u}}(z, t)] \end{aligned} \quad (3)$$

172 where  $\dot{f}$  represents the time derivative of function  $f$ ,  $\rho$  is the water density,  $\mathbf{v}$  and  $\mathbf{a}$  are wave velocity and  
 173 acceleration vectors, and  $\mathbf{u}$  is the structure rigid body motion vector. The added mass and drag coefficients  
 174  $C_a$  and  $C_d$  generally depend on Keulegan-Carpenter and Reynolds numbers [35] but they can be assumed  
 175 constant if the following condition is fulfilled [27]:

176 
$$R_e > 10^4 K_C \quad (4)$$

Condition (4) is generally satisfied for full-scale offshore wind turbine spar under all the most relevant wave conditions [23], but the same may not be true for the corresponding small-scale models. Indeed, the Reynolds number scales with a factor equal to  $\lambda_L^{1.5}$ , hence condition (4) may be violated for smaller models, resulting in scale effects due to the alteration of the hydrodynamic coefficients, which describe wave-structure interaction (see, for example references [36-37]).

Other challenges related with the scaling of floating structures concern the mass distribution of the structure and the mooring system. It is almost impossible, indeed, to scale down exactly all the structural properties, e.g. wall thickness, because manufacturing as well as strength requirements of the scale model must be taken in due consideration. Hence, in general it shall be ensured that the scale model matches the full-scale structure in terms of global properties such as mass, position of the centre of gravity, mass moments of inertia and mooring linearized stiffness. Also in this case, the smaller is the model, the more challenging is to fulfil these requirements.

### 2.3 Description of the 1:30 spar model

The OC3-Hywind spar buoy is basically a vertical tapered cylinder, moored to seabed by three catenary lines, and supporting the NREL-5MW reference offshore wind turbine [14]. The 1:30 model installed at NOEL (Fig. 2) is made up of a steel hull and an aluminium tower, separated by a plastic disc to avoid galvanic corrosion. The hull has been ballast-stabilized by steel discs deployed in its lower section, so that the required position of the centre of gravity has been achieved. The rotor-nacelle assembly (RNA) has been modelled as a lumped mass at the top of the tower. The main geometry and mass characteristics are reported, respectively, in Table 2 and Table 3, while some additional details on the design of the model are described in Ref. [23].

198

Figure 2 – Spar hull model before (left) and after (right) installation, sustaining the parked turbine model [29]

Table 2 – Geometry of the structure at model scale and full scale and comparison with the OC3-Hywind.

<i>Parameter</i>	<i>Units</i>	<i>Scale model (1:30)</i>	<i>Full-scale structure (1:1)</i>	<i>OC3-Hywind (1:1)</i>
Diameter	m	0.217; 0.313	6.51; 9.39	6.50; 9.40
Draft	m	3.884	116.5	120.0
Centre of buoyancy, vertical position (from SWL)	m	-1.974	-59.21	-62.06
Taper, vertical position	m	-0.020; -0.287	-0.61; -8.62	-4.00; -12.00

(from SWL)				
RNA, vertical position (from SWL)	m	3.080	92.39	90.00

202

203 *Table 3 – Mass characteristics of the structure at model scale and full scale and comparison with the OC3-*  
204 *Hywind.*

<i>Parameter</i>	<i>Units</i>	<i>Scale model (1:30)</i>	<i>Full-scale structure (1:1)</i>	<i>OC3-Hywind (1:1)</i>
Total mass	kg	297.0	$8.02 \cdot 10^6$	$8.07 \cdot 10^6$
Centre of gravity, vertical position (from SWL)	m	-2.496	-74.88	-78.00
Moment of inertia about x-axis (respect to the CoG)	kg m <sup>2</sup>	994.9	$2.42 \cdot 10^{10}$	$2.30 \cdot 10^{10}$
Moment of inertia about y-axis (respect to the CoG)	kg m <sup>2</sup>	995.0	$2.42 \cdot 10^{10}$	$2.30 \cdot 10^{10}$
Moment of inertia about z-axis	kg m <sup>2</sup>	4.870	$1.18 \cdot 10^8$	$1.91 \cdot 10^8$

205 Based on condition (4), it is possible to estimate how hydrodynamic coefficients of Morison's equation are  
206 altered by the scale factor chosen. To this aim, Fig. 3 shows how the ratio between Reynolds number and  
207 Keulegan-Carpenter number varies with the scale factor for the spar support considered, assuming the  
208 wave peak period  $T_p$  at full scale as the characteristic period  $T$  and the diameter of the surface-piercing  
209 section of the spar hull as the characteristic length  $D$  in equations (1-2).

210

211 *Figure 3 – Variation of  $R_e/K_C$  ratio depending on the scale factor.*

Fig. 3 confirms that the distortion of Reynolds number at 1:30 scale is rather limited, so that a correct representation of the hydrodynamic coefficients can be achieved in the whole range of peak periods considered. Differently, 1:50 models may present slight alterations of the hydrodynamic coefficients for the highest periods (scaled representation of severe storms and swells) and 1:100 models significantly alter Reynolds number, resulting in a distortion of wave forces in the whole range of realistic wave peak periods. This is a significant advantage of intermediate-scale open-sea field experiments in terms of representation of the actual dynamic behaviour of spar floating supports for offshore wind turbines.

The mooring system of the model structure has been designed considering the irregular and inclined seabed at the NOEL site, and the local harshest metocean conditions. It is based on the full-scale mooring system design of UMaine-Hywind spar [38], which is equivalent to OC3-Hywind but intended for a water depth of 200 m instead of 320 m. This reference design, however, has been used only for defining the shape of the mooring system, i.e. three 120°-spaced catenary lines, and the weight per unit length of each line. Differently, the position of the anchors and the length of the lines have been set so as to match local bathymetry and to ensure structure safety under local extreme conditions. Consequently, the resulting mooring system of the model has longer mooring lines and smaller stiffness with respect to the full-scale UMaine Hywind spar structure. Moreover, the model mooring system is asymmetric, due to the different water depths of the sea-side and land-side anchors. The design of each line has been carried out through an in-house quasi-static numerical code, based on the particularization of the catenary equation to inclined seabed conditions. Let us consider a 2-D reference system  $Ax'z'$  in the plane of the catenary line, originating in the anchor point A and pointing towards the structure ( $z'$  positive upwards). Then, the catenary equation may be written as:

$$z'(x') = \frac{F_{x'}}{w} \cosh \left[ \frac{w}{F_{x'}} x' + \operatorname{arcsinh}(\tan \beta_A) \right] - \frac{F_{x'}}{w} \sqrt{1 + \tan^2 \beta_A} \quad (5)$$

being  $F_{x'}$  the horizontal tension of the line,  $w$  the weight per unit length and  $\beta_A$  the inclination at the anchor point. At the same time, in the local curvilinear system of the line  $Asn$  ( $s$  positive towards the structure), the shape of the line may be expressed as:

$$s(x') = \frac{F_{x'}}{w} \sinh \left[ \frac{w}{F_{x'}} x' + \operatorname{arcsinh}(\tan \beta_A) \right] - \frac{F_{x'}}{w} \tan \beta_A \quad (6)$$

The quasi-static shape and restoring force of each line has been obtained as a function of surge and sway structure motions by combining equations (5-6) and the boundary conditions, i.e. the fixed position of the anchor, the variable position of the structure and the length of the line. The resulting restoring forces of the three lines for each structure configuration have been summed in the global 3-D reference system  $Gxyz$ , to obtain the global restoring forces for the structure. The final design of the lines has been obtained through a trial-and-error procedure to achieve the desired stiffness. The resulting characteristics of the mooring system are reported in Table 4, while Fig. 4-5 show the restoring forces as functions of the surge and sway motions of the model. Although these forces are nonlinear, linearized surge and sway stiffness can be defined as the tangent stiffness of the force-motion function in the equilibrium position. The corresponding linearized behaviour is reported in Fig. 4-5 too. In the installation phase, the yaw stiffness has been enhanced through a delta connection of the mooring lines. The length of each side of the delta has been set equal to about 10% of the corresponding line length, following the practical instructions of Quallen et al.

250 [39]. Additional details on the numerical model used for the design of the mooring system of the model  
 251 may be found in Ref. [23]. A picture of the mooring system taken after installation is shown in Fig. 6.

252 Table 4 – Characteristics of the mooring system of the model structure.

Parameter	Units	Model (1:30)	
		Sea-side	Land-side
Fairleads, vertical position (from SWL)	m	-2.224	-2.224
Anchor depth	m	10.40	2.75
Seabed inclination	°	14.21	18.09
Linear mass of the line	kg m <sup>-1</sup>	0.159	
Radius anchor-spar centreline	m	14.04	12.92
Line length	m	16.56	13.30
Delta connection length	m	1.50

## 263 2.4 Measurement systems

264 The experimental activity has been carried out using two independent measurement systems.

265 The first measurement system is for wave data collection, and is made up of two fixed poles, installed close  
 266 to the spar model, in an undisturbed wave field. Each pole sustains an emerged ultrasonic probe, to  
 267 measure the time history of the wave surface elevation at a fixed point, and a submerged pressure  
 268 transducer, to measure the wave pressure time history at the same point, at an average depth of 0.78 m.  
 269 The four sensors have been synchronized and the correlation factor between ultrasonic probes and

270 pressure transducers output has been estimated for each sea state, resulting generally greater than 0.85.  
271 However, the ultrasonic probes experienced some temporary breakdown (about 28% of data), hence the  
272 pressure transducers have been used for the estimations of the wave spectra, due to their greater  
273 reliability. Significant wave height, wave spectrum and mean propagation direction for each sea state have  
274 been obtained following the methods described in Ref. [27]. Also, the tide variation of the sea level has  
275 been calculated for each sea state.

276 The second system is devoted to the measure of the spar dynamic response, and is composed of a  
277 differential global positioning system (DGPS), which returns the position of the structure with respect to a  
278 fixed point on the land, and an Attitude and Heading Reference System (AHRS) inertial platform, which  
279 measures the inclination of the platform with respect to the three axes.

280 The two measurements systems have been synchronized, and both have a sampling frequency of 10 Hz.

## 281 **2.5 Numerical model of the structure**

282 A numerical model of the spar structure has been implemented in ANSYS AQWA (v. 16.1) [26], and has  
283 been calibrated with experimental data collected at NOEL. The whole numerical model has been  
284 implemented at 1:1 scale, which returns an immediate comparison with OC3-Hywind full-scale structure.

285 Following the approach of Jonkman [14], the hydrodynamic loads have been modelled adopting a potential  
286 theory approach, augmented by the drag term of Morison's equation. According to Jonkman, delta  
287 connections of the mooring lines have been represented through an additional yaw stiffness equal to  $K_{\delta\delta} =$   
288  $9.834 \cdot 10^7 \text{ Nmrad}^{-1}$ , and the linear additional damping coefficients  $B_{11} = B_{22} = 1.000 \cdot 10^5 \text{ Nsm}^{-1}$ ,  $B_{33} =$   
289  $1.300 \cdot 10^5 \text{ Nsm}^{-1}$ ,  $B_{\delta\delta} = 1.300 \cdot 10^7 \text{ Nsmrad}^{-1}$  have been added. Initially, the additional damping matrix has  
290 been set by Jonkman based on small-scale free decay tests operated by Statoil on a model of the Hywind  
291 platform. Then, the additional damping matrix has been calibrated in Section 3.2, using the experimental  
292 data collected on the 1:30 model installed at NOEL. The hull has been represented through a "Point mass"  
293 item (Table 3), and the mesh includes 6735 diffracting elements (Fig. 7) and 104 line bodies, which are used  
294 to include the viscous drag forces. The mooring system has been represented by three catenary lines on a  
295 constant water depth of 200 m, sized so that linearized horizontal stiffness is equivalent to the value  
296 reported in Table 4 for the structure installed at NOEL.

### 3. Results of the experimental activity

The experimental activity on the 1:30 model of OC3-Hywind platform started in July 2015 and was concluded in March 2016. An overall number of 1281 5-minute-long wave and motion records was collected selecting the widest range of local wave conditions possible. The scatter diagrams of significant wave heights with respect to peak periods are shown in Fig. 8.

Figure 8 – Scatter diagram of the significant wave heights recorded at NOEL with respect to peak period.

Wave data collected include both wind-generated local sea states, swells and mixed sea states. The wind-generated sea states are useful for the representation of the scaled behaviour of OC3-Hywind in severe wave conditions, while the other ones are important for the determination of the spar characteristics in the frequency domain. The discrimination criterion adopted in Fig. 8 to distinguish wind-generated data is the following:

$$\begin{cases} \psi^* > 0.65 \\ gK_{\min}T_p^2 < H_s < gK_{\max}T_p^2 \end{cases} \quad (7)$$

being  $\psi^*$  the narrow-bandedness parameter of the wave head of pressure spectrum defined as in Ref. [27],  $g$  the acceleration due to gravity and  $K_{\min}$ ,  $K_{\max}$  two steepness parameter. The narrow-bandedness parameter is obtained as the module of the minimum of the auto-covariance function of the wave pressure time series, normalized to the maximum of the same function, and tends to unity as the spectrum tends to be infinitely narrow. The first condition in (7) is hence aimed to exclude the mixed sea states, which are relatively broad-banded. The second condition is instead aimed to exclude pure swells, whose steepness is significantly lower than that of wind waves. The limit values of the steepness parameters used in (7) have been derived by Arena et al. [40], considering the whole range of shape parameters of the JONSWAP spectrum, which is representative of wind-generated waves [41]. The resulting limit values are  $K_{\min} = 4.057 \cdot 10^{-3}$  and  $K_{\max} = 9.246 \cdot 10^{-3}$ . Overall, 139 wind-generated sea states have been selected from the whole set of 1281 data, using the dual criterion in (7).

### 3.1 Damping estimations from free decay tests

An estimation of the natural frequencies and damping coefficients of the 1:30 model in heave, roll and pitch has been firstly obtained through free decay tests performed at sea, in sufficiently calm wave conditions ( $H_s \leq 0.11$  m). The procedure for the realization of the tests has been described in Ref. [24]. With respect to the traditional free decay tests carried out in ocean basins, the continuous irregular wave action alters the smallest decay cycles, making the tests shorter and slightly coarser.

The method adopted in this paper for the estimation of damping coefficients is derived from Ref. [42], where extensive description of the method and alternative formulations may be found. In synthesis, for each free decay test, each degree of freedom is treated as uncoupled and thus the corresponding 1-DOF equation of motion is:

$$(M_{ii} + A_{ii})\ddot{u}_i + B_{ii}\dot{u}_i + D_{ii}|\dot{u}_i|\dot{u}_i + C_{ii}u_i = 0 \quad (8)$$

$u_i$  being the degree of freedom (DOF) involved in the free decay test,  $M_{ii}$  the corresponding term in the inertia matrix,  $A_{ii}$  the hydrodynamic added mass,  $C_{ii}$  the stiffness term,  $B_{ii}$  the linear damping coefficient and  $D_{ii}$  the non-linear damping coefficient. Equation (8) implicitly assumes that the DOFs are not coupled, which is realistic for heave, pitch and roll. By equating the work done by the restoring moment and the energy dissipated by linear and nonlinear damping for each half-cycle (positive or negative) one obtains:

$$\Delta u_{i,peak} = p_1 u_{i,mean} + p_2 u_{i,mean}^2 \quad (9)$$

$$p_1 \equiv \frac{\pi}{2\omega_{n,ii}} \frac{B_{ii}}{(M_{ii} + A_{ii})} \quad (10)$$

341

$$p_2 \equiv \frac{4}{3} \frac{D_{ii}}{(M_{ii} + A_{ii})} \quad (11)$$

342

343

$\omega_{n,ii}$  being the natural frequency, which can be read from the test,  $u_{i,mean}$  the mean displacement value between two successive peaks (positive or negative) of the test and  $\Delta u_{i,peak}$  their difference.

344

345

346

347

348

349

350

351

In total, 17 free decay tests have been conducted in heave, and 10 in roll/pitch (Fig. 9). Equation (9) has been fitted to the experimental data collected from all the free decay tests, obtaining the curves shown in Fig. 10 and Fig. 11, respectively. The resulting estimations in terms of natural frequencies and linear damping coefficients are reported in Table 5. Interestingly, the estimates of the linear damping coefficients are larger than those suggested by Jonkman [14], which were based on the results of free-decay tests performed on a small-scale model of Statoil's Hywind. This may be due to the relatively large scale of the model, which allows to reduce the scale effects and to obtain a more reasonable approximation of the actual values to be used for the modelling of the full-scale structure.

352

353

354

355 Figure 10 – Fitting of Equation (9) to experimental data for the heave degree of freedom.

356

357 Figure 11 – Fitting of Equation (9) to experimental data for the roll degree of freedom.

358

359 Table 5 – Experimental estimation of natural frequencies and linear damping coefficients via free decay  
360 tests.

Degree of freedom	$\omega_n$ [rad/s]		$B_n$ [kg s <sup>-1</sup> ; kg m <sup>2</sup> s <sup>-1</sup> rad <sup>-1</sup> ]	
	Model scale (1:30)	Full-scale (1:1)	Model scale (1:30)	Full-scale (1:1)
Heave	1.090	0.199	153.6	7.570·10 <sup>5</sup>
Roll/Pitch	1.006	0.202	228.5	1.014·10 <sup>9</sup>

361 The nonlinear damping coefficient  $D_{roll}$  has been used instead for the indirect estimation of the  
362 hydrodynamic drag coefficient  $C_d$  of the hull. It is obtained by equating the nonlinear term of equation (8)  
363 and the drag term of the roll moment about the centre of gravity, given by Morison's equation (3). Wave  
364 elevation and spar motions in surge and heave have been neglected, so to obtain:

365

$$C_d = \frac{D_{roll}}{\rho \int_{z_{min}}^0 R(z) |z - z_G| (z - z_G)^2 dz} \quad (12)$$

366  $z_{min}$  and  $z_G$  being the draft and the centre of gravity position of the model structure, respectively. The  
367 resulting value is  $C_d = 1.998$ , which is consistent with the expected one for calm water conditions [37]. This  
368 represents a further confirmation of the feasibility of Morison's equation for the representation of viscous  
369 drag hydrodynamic forces on the spar structure.

370

### 371 3.2 Irregular wave tests: RAOs and damping estimations

372 A further stage of the model identification has been achieved through the analysis of the spar response to  
373 the irregular waves recorded at the test site. The RAOs of the model have been estimated from the  
374 experimental data and the numerical model in Ansys AQWA has been calibrated, by setting the linear  
375 damping coefficients such that the numerical RAOs fit well the experimental ones. Concerning the  
376 nonlinear damping, it has been represented through the drag term of Morison's equation, using a constant  
377 drag coefficient  $C_d = 0.6$ , representative of the spar behaviour in moderate to severe irregular waves [14],  
378 as those measured during the experiment (Fig. 8).

379 The determination of experimental RAOs in open sea cannot be achieved as in ocean basins, where regular  
380 waves and irregular sea states, with the desired broad-banded spectra, can be generated. Consequently, an  
381 alternative method for the estimation of the RAOs has been developed and applied to the data collected  
382 during the experimental activity, as described below. The relationship between a wave spectrum and the  
383 corresponding structure response spectrum, in a given DOF  $u$ , is expressed by:

384

$$E_u(\omega) = RAO_u^2(\omega) E_\eta(\omega) \quad (13)$$

385 The inverse relationship of equation (13) would give a well-defined estimation of the RAO in the whole  
 386 frequency domain only when using white noise spectra as input. However, in practice, each sea state has a  
 387 limited energy content in the frequency domain, i.e. is narrow-banded. For this reason, only the portion of  
 388 the frequency domain with enough energy content (see Appendix) has been considered for the estimation  
 389 of experimental RAOs, depending on the wave spectrum of the sea state considered. Following these  
 390 considerations, each sea state provides information about the RAOs on a limited range of frequencies and a  
 391 global estimation of the RAOs over the whole frequency domain may be obtained only by averaging over  
 392 and putting together a sufficient number of data, each contributing to its own frequency range. The  
 393 expression used in this paper for the estimation of each of these contributions is:

$$394 \quad RAO_u(\omega) = \sqrt{\frac{E_u(\omega)}{E_{\eta,ph}(\omega)}} \frac{\cosh[k(d + z_{PT})]}{\cosh(kd)} \Leftrightarrow E_{\eta,ph}(\omega) \geq \alpha E_{\eta,ph}(\omega_p) \quad (14)$$

395 being  $E_u$  the motion response spectrum in the  $u^{\text{th}}$  degree of freedom,  $k(\omega)$  the wave number,  $d$  the water  
 396 depth,  $z_{PT}$  the distance of the pressure transducer from the still water level,  $\omega_p$  the peak frequency of the  
 397 wave spectrum, and  $\alpha$  a positive parameter smaller than unity. In the present study, the value chosen for  
 398 such parameter is  $\alpha = 0.10$  and the portion of the frequency domain considered for the estimation of the  
 399 RAOs is  $\omega = (0.80 - 4.10)$  rad/s at model scale (1:30), which corresponds to about  $\omega = (0.15 - 0.75)$  rad/s at  
 400 full scale (1:1). Both these values have been calibrated through a parametric analysis, which is described in  
 401 the Appendix. It should be noted that wave head of pressure spectra  $E_{\eta,ph}$  have been used in equation (14)  
 402 instead of wave surface elevation ones  $E_\eta$ . This is because it has been observed that pressure transducers  
 403 guarantee greater reliability with respect to ultrasonic probes. The attenuation factor, which depends on  
 404 the distance  $z_{PT}$  of the pressure transducer from the still water level, has been then used to refer the  
 405 resulting RAO contributions to the wave surface elevation, as it is common practice in offshore engineering.

406 Due to the axial symmetry of the spar, for the heave RAO estimation it has been possible to use the whole  
 407 experimental dataset collected at NOEL, i.e. the 1281 sea states and the corresponding time histories of the  
 408 model structure response, while a selection based on the mean propagation direction value has been made  
 409 for the estimation of roll and pitch RAOs. In particular, only the sea states with mean propagation  
 410 directions between  $-40^\circ$  and  $0^\circ$  with respect to the North have been included in the dataset considered,  
 411 obtaining a total number of 824 sea states. The calibration of the numerical model has been made by  
 412 setting the linear damping coefficients such that the peaks of the numerical RAOs approximately  
 413 correspond with those of the experimental ones. The estimates obtained through the free decay tests have  
 414 been used for starting the trial and error fitting procedure. The numerical RAOs used for the calibration  
 415 process have been obtained in ANSYS AQWA through a linearization process, performed on a sea state with  
 416 significant wave height of 6 m, mean-JONSWAP spectrum (averaged as in Ref. [27]) and wave propagation  
 417 direction of  $-20^\circ$  (1:1 scale). The resulting experimental and numerical RAOs in heave, roll and pitch at the  
 418 model scale (1:30) are shown, respectively, in Fig. 12-14. The estimated peak frequencies and damping  
 419 coefficients are instead reported in Table 6.

420  
421 Figure 12 – Experimental and numerical heave RAOs at model scale (1:30).

422  
423 Figure 13 – Experimental and numerical roll RAOs at model scale (1:30).

Table 6 – Experimental estimation of natural frequencies and linear damping coefficients via irregular wave tests.

Degree of freedom	$\omega_n$ [rad/s]		$B_n$ [kg s <sup>-1</sup> ; kg m <sup>2</sup> s <sup>-1</sup> rad <sup>-1</sup> ]	
	Model scale (1:30)	Full-scale (1:1)	Model scale (1:30)	Full-scale (1:1)
Heave	1.047	0.191	50.72	2.500·10 <sup>5</sup>
Roll	0.963	0.176	89.03	3.950·10 <sup>8</sup>
Pitch	0.963	0.176	183.7	8.150·10 <sup>8</sup>

Natural frequency estimations obtained via free decay tests (Table 5) and irregular wave tests (Table 6) are consistent to each other, while small differences are observed with respect to the numerical predictions, based on the model characteristics reported in Table 2-3. In particular, the peak frequencies of numerical RAOs are slightly larger than those observed experimentally and the difference is of about 2.5 % for heave and of about 8.1 % for roll and pitch. This is probably due to the inevitable uncertainties introduced in the computation of the mass and mass distribution of the model by multiple causes, including welding and manufacturing procedures, use of non-structural elements such as sensor cables, marine growth and so on. As a result, mass and mass moment of inertia reported in Table 3 are slightly underestimated, resulting in the corresponding overestimation of the natural frequencies.

Linear damping coefficients estimated through irregular waves (Table 6) are instead smaller than those estimated through free decay tests (Table 5), while they are still greater than those predicted by Jonkman [14], based on free decay tests carried out in a small-scale experimental activity. This result leads to interesting conclusions about the feasibility of the free decay tests for the estimation of the model damping coefficients. The estimation of  $B_n$  performed by free decay tests is indeed referred to calm water conditions, is based on the hypothesis of uncoupled motions and takes into account the damping properties of the model only around its natural frequencies. Differently, estimation performed through experimental RAOs allow to investigate directly the coupled dynamic behaviour of the model in irregular

445 waves and extends the analysis over a wider frequency range. For these reasons, the latter approach  
446 provides more accurate results, which should be used for the calibration of the hydrodynamic numerical  
447 models. This encourages the realization of intermediate-scale open-sea experiments on floating supports  
448 for offshore wind turbines, since they can provide information concerning the structure dynamic behaviour  
449 under relevant wave conditions and at relatively large scales.

450 Another interesting consideration concerns the difference observed in roll-pitch linear damping coefficients  
451 estimated through irregular waves (Table 6). Although the model presents some minor asymmetries due to  
452 the mooring system and the on-board measurement station, the main cause for that is the directionality of  
453 the sea states used for the estimation of the RAOs. Each sea state has indeed different mean propagation  
454 directions, which are not uniformly distributed in the range  $(-40^\circ; 0^\circ)$ , and directional spreading functions.  
455 On the opposite side, the sea state used in the numerical model has a single propagation direction  $(-20^\circ)$   
456 and no directional spread. In both cases, the dominant rotation of the model is pitch, since the mean  
457 propagation direction is close to  $0^\circ$ , however this effect is mitigated in the experiment, where the variability  
458 of the mean propagation direction and the directional spread cause an increase of roll motions and a  
459 reduction of pitch ones. Consequently, the calibration of the model results in an overestimation of pitch  
460 linear damping coefficient, since the directionality of the measured sea states acts as a fictitious additional  
461 damping, and in an underestimation of the roll linear damping coefficient, for the opposite reason. The two  
462 values obtained for the damping coefficients may be indeed seen as upper and lower bounds, respectively,  
463 for pitch/roll linear damping of the spar support. In general, more accurate estimations can be obtained by  
464 recording more data, which would allow a finer discretization of the measured wave directional range for  
465 the calibration of the numerical model. Differently from roll and pitch, it should be also noted that  
466 directionality has no effect in the heave RAO, since heave motion is not affected by wave propagation  
467 direction, due to the axial symmetry of the structure.

468 The main drawback of the approach proposed is that no prediction concerning the model structure  
469 behaviour could be made outside the envelope of the frequency ranges of the sea states considered ( $\omega =$   
470  $0.80 - 4.10$  rad/s), due to the scarcity of sea states with sufficient energy content at the corresponding  
471 frequencies. Consequently, the dynamic identification of the model in surge, sway and yaw degrees of  
472 freedom could not be realized through the experimental estimation of the RAOs. Nevertheless, some useful  
473 considerations could be drawn from the spectral analysis of these motions. The power spectral densities  
474 have been calculated for the whole set of 1281 records and the mean and top-third averaged surge and  
475 sway spectra are shown in Fig. 15-16, respectively.

476

477 *Figure 15 – Mean and top-third averaged surge response spectra of the whole dataset of 1281 sea states*  
 478 *recorded during the experiment.*

479

480 *Figure 16– Mean and top-third averaged sway response spectra of the whole dataset of 1281 sea states*  
 481 *recorded during the experiment.*

482 The averaged power spectral densities shown in Fig. 15.16 may be divided in various regions, corresponding  
 483 to different contributions. The first region ( $\omega < 0.1$  rad/s) is that of slow-drift motions, which may be  
 484 induced by wind, currents and/or tidal, as well as by slow-drift wave forces. The second region corresponds  
 485 to surge and sway natural frequencies, which are equal to each other:  $\omega_1 = \omega_2 = 0.168$  rad/s. This result  
 486 confirms that the stiffness values in surge and sway are close to each other, in spite of the geometric  
 487 asymmetry of the mooring system. It should be also noted that the range of natural frequencies of the

individual power spectral densities span from  $\omega = 0.147$  rad/s to  $\omega = 0.189$  rad/s. This is due to the nonlinear mooring stiffness and to the randomness of wave energy content distribution (thought small) in the corresponding frequency range. The third region shows the coupling between surge/sway and pitch/roll, as well as a small coupling with heave motion. The frequencies of the corresponding peaks in Fig. 15-16 are respectively  $\omega = 0.963$  rad/s to  $\omega = 1.089$  rad/s, which are consistent with the values reported in Tables 5-6. Also in this case, the individual power spectral densities show a variability of the natural frequencies, which is due to nonlinear effects and should be further addressed in further time-domain analyses of the experimental results. Finally, the fourth region ( $\omega > 1.1$  rad/s) corresponds to the wave-induced motions, which are smaller than the other contributions in average but are significant for individual wind-generated sea states. Although the analysis of response spectra gives some clear information about the dynamic behaviour of the model in surge and sway degrees of freedom, it could not be used for direct estimation of the corresponding linear damping coefficients necessary for the calibration of the numerical model. To this aim, the Authors proposed an alternative identification method [43], based on the adoption of output-only identification techniques, borrowed from Operational Modal Analysis. This approach has already proved successful for the dynamic identification of a numerical model of a spar structure, similar to the present one, and may be hence used in future studies to complement the identification process of the intermediate-scale models of offshore structures installed at sea.

505

## 506 Conclusions

This paper presents the results of an experimental activity on a 1:30 scale model of a spar floating support structure (OC3-Hywind) for offshore wind turbines, in parked rotor conditions. The experiment was conducted at sea, in the Natural Ocean Engineering Laboratory of Reggio Calabria (Italy), between July 2015 and March 2016. The aim of the experiment was to investigate the feasibility of intermediate-scale, open-sea experimental activities on floating support structures for offshore wind turbines, which may overcome some of the most relevant limitations of the traditional small-scale ones, namely the high costs, the introduction of significant scale effects, and the limited duration of the experimental campaigns. Traditional identification techniques, commonly adopted in wave tanks and ocean basins, could not be directly applied to the interpretation of the experimental data, due to the non-controlled nature of the marine environment, hence they have been opportunely modified to meet the requirements of the application considered. 1281 5-minutes long sea states, including wind-generated waves, mixed sea states, and swells have been measured, and they have been used to perform the dynamic identification of the model considered, and to calibrate its numerical model, implemented in ANSYS AQWA. The main conclusions are:

- An optimised approach for intermediate-scale, open-sea experiments of floating offshore wind turbines has been proposed. In particular, the requirements of a suitable test site have been identified, and some identification techniques compatible with the non-controlled marine environment have been proposed.
- The free decay tests provided a good estimation of the natural frequencies of the model, but proved to overestimate the linear damping coefficients.
- The irregular wave tests were used to estimate the natural frequencies, damping coefficients and Response Amplitude Operators (RAOs) in the operational wave conditions of the model. The experimental RAOs obtained match well with the numerical predictions, and allowed to calibrate the numerical model.

- The limited frequency range of the natural sea states recorded at the test site resulted in the impossibility of identifying the dynamics of the model over the complete frequency range. This is an intrinsic limitation of the open-sea experiment, when traditional input-output identification techniques, such as those presented in this paper, are applied. Due to this limitation, experimental RAOs estimation and numerical model calibration could be performed only for heave, roll and pitch degrees of freedom of the model.
- Some alternative approaches have been proposed to overcome the above limitations. Spectral analysis of surge and sway motions has proved to be suitable for identifying the corresponding natural frequencies and the most relevant dynamic characteristics. Finally, output-only identification techniques typical of Operational Modal Analysis [43] have been suggested as potential alternative/complementary methods for the full identification of intermediate-scale models of floating structures installed at sea.

## 654 A. Appendix

655 Parameter  $\alpha$  of equation (14) has been calibrated through a parametric analysis on the whole dataset  
656 collected during the experiment. Ideally speaking, the domain of meaningful values for this parameter  
657 ranges from 0 to 1. In the limit case of  $\alpha = 0$ , the response spectra of each sea state would be used for the  
658 determination of the RAOs in the whole frequency domain, including the portions where the wave  
659 spectrum ordinates are very small and their estimation is not accurate, due to the unavoidable numerical  
660 inaccuracies. Such a case would result in RAOs tending to infinite in these portions, and generally in strong  
661 inaccuracies in their estimation. In the opposite limit case of  $\alpha=1$ , only the peak spectral ordinates would be  
662 used for the determination of the RAOs, resulting in a single point in the frequency domain for each sea  
663 state. While in this case the numerical inaccuracies in the spectrum determination would be negligible, the  
664 resulting estimation of the RAOs would be limited to few points in the frequency domain. In this study, the  
665 value of  $\alpha$  has been set equal to 0.10 after a parametric analysis, aimed to evaluate its effect on the  
666 estimation of experimental RAOs. Similarly, frequency range has been limited to  $\omega = (0.8 - 4.0)$  rad/s (1:30  
667 scale), due to the scarcity of data out of this range.

668 The parametric analysis has been conducted by estimating the experimental RAOs for six different values of  
669 the parameter  $\alpha$  of equation (14), ranging from 0.10 to 0.60. At this stage, the six estimates of the RAOs for  
670 each of the three degrees of freedom have been plotted on the frequency range  $\omega = (0.0 - 5.0)$  rad/s. The  
671 results obtained are shown in Fig A1-A3.

672

673 Figure A1 – Experimental heave RAOs obtained for different values of  $\alpha$  (1:30 scale).

674

675 Figure A2 – Experimental roll RAOs obtained for different values of  $\alpha$  (1:30 scale).

676

677 *Figure A3 – Experimental pitch RAOs obtained for different values of  $\alpha$  (1:30 scale).*

678 Concerning the frequency range, as expected, the number of contributions (eq. 14) available for the  
 679 averaging procedure is too small for the smallest and highest frequencies, resulting in inaccurate  
 680 estimations in the corresponding portions of the frequency domain. Basing on the analysis of the wave data  
 681 available (Fig. 8), the frequency range  $\omega = (0.80 - 4.10)$  rad/s has been chosen for the estimation of the  
 682 RAOs. It corresponds to a maximum wave period of about 8 s, which is consistent with the wave conditions  
 683 observed at NOEL site (Fig 8). In the selected frequency range, the global shape of the RAOs is not  
 684 significantly altered by the variation of  $\alpha$ . This confirms the robustness of the calculation procedure,  
 685 provided that sufficient wave data are available. However, the RAOs corresponding to  $\alpha = 0.10$  are  
 686 significantly smoother than the other ones. This is due to the fact that larger values of  $\alpha$  involve a  
 687 significant decrease of the number of contributions (eq. 14) to the average estimate at certain frequencies.  
 688 This phenomenon is particularly evident for the roll RAO at the frequency  $\omega = 1.089$  rad/s. As a  
 689 consequence, for the case study considered, the value  $\alpha = 0.10$  has been chosen. Higher values for  $\alpha$  can be  
 690 used by increasing the number of samples in the dataset used in the calibration.
